1 Introduction

General problem: two types of services, on-demand and fixed-line => explain why we focus on fixed line (all constraints of the platform) Fixed line because now roads are not made for more complex systems

2 Related Literature

The scope of vehicle scheduling problems related to our specific case study can range from fixed-line bus services to on-demand systems. In fact, electric shuttles' routes and stops are predefined but timetables can be flexible to respond to the known real-time demand. The set of constraints differs from traditional bus transportation, for example workforce regulations can be eliminated as the shuttles are not human driven but a battery management component needs to be introduced into the planning process. As we will see in this chapter, current research often concentrates on one specific aspect of the scheduling strategy, simplifying some constraints, assessing the system's performance using various types of metrics and considering different inputs. In what follows, we describe in section 2.1 some techniques used in the traditional public transport industry to guarantee a good quality of service. In section 2.2 we describe the concept of Demand-Adaptive Transit Systems. Finally, we detail in section 2.3 an approach proposed by the Urban Transport Systems Laboratory at EPFL (LUTS) for scheduling autonomous vehicles activities.

2.1 Public Transport

Within the standard transit organization, policies and standards affect a lot the development of transport strategies and how people interact with the systems. The planning process of a fixed line bus transportation service is mainly composed of three different tasks: route planning, service frequencies and service timing. Route planning consists of defining a sequence of stops composing each route and how those routes are interconnected. Service frequency captures the number of vehicles per unit time which pass a given route (often expressed in vehicles per hour). A common measure used to express the ideal distance between vehicles is the headway, the inverse of the frequency, in other word the fixed interval at which vehicles are coming at a station. The service frequencies set by the transport organization can be chosen based on different policies (see Pine et al. (1998)):

- 1. **Fixed headway**: the agency establishes a fixed interval at which vehicles come to stations. It is convenient for customers as they have access to an exact schedule, but it is hard to keep the time between vehicles constant as it is vulnerable to external disturbances.
- 2. **Demand-based headway**: in existing transport services, agencies can adapt the timetables based on the observed demand at the stations (number of passenger boardings/deboardings) in order to reach the desired passenger load in vehicles.
- 3. **Performance-based headway**: the goal is to find the headway for which performance standards are optimized. Those costs are usually measured during a

service period, for example a day. It may include the service productivity (e.g. the revenue per passenger per hour), the cost effectiveness of the service or the overall effectiveness (e.g. net subsidy per passenger).

All those scheduling strategies suffer from the well-known bunching effect: two or more buses arrive at the same time at a stop with the first one being overcrowded and the other one empty. This phenomenon occurs because of external disruptions in the service (e.g. stochastic passenger arrivals at stops, traffic jams, etc) (see Camps and Romeu (2016)) slowing down one of the bus which pick up passengers who would have taken the next bus.

Several corrective measures based on different strategies have been developed to overcome this problem. There are mainly two different holding approaches to mitigate bus bunching as described in van Oort et al. (2010):

- Headway-Based Holding: vehicles arriving with a shorter headway at a stop (or holding point) wait to restore the headway distribution. If they arrive with a longer headway, it is possible to speed up the buses by skipping stations. The analytical study Cortés et al. (2010) proved the efficiency of using headway holding strategy and bus skipping (considering the extra waiting time of passenger whose station has been skipped) with the two-dimensional objective function composed of the regularization of bus headways on the one hand and the level of service with respect to a circle route scenario.
- Schedule-Based Holding: in the case of fixed timetables, schedule-based holding involves holding a vehicle at a stop if it is ahead of its schedule and dispatch it immediately otherwise.

Zhao et al. (2016) proposed a method using boarding limits at stations to control buses which does not involve bus accelerating or waiting at stations and thus does not influence the customers' travel time and does not disturb the traffic. They do not consider schedule and a priori target headway. However, they proved that their self-adjusting control stabilizes the headway spontaneously in a short time.

Adra et al. (2004) study the importance of the vehicle load effects on the emission of vehicles through the study of the load factor and the empty running rate. The passenger load factor measures the efficiency of a transportation system, representing the capacity utilization of the seats. It is often expressed as the ratio between the passenger-kilometres travelled to seat-kilometres available.

As stated by He (2015), the majority of earlier studies conducted on maintaining a balanced headway uses arrival time of the current bus at the current stop and arrival times of the preceding buses but does not take advantage of real time information like the vehicles' geolocation. Later methods proposed new approaches assuming availability of locations and even real-time arrivals of passengers to each bus stop. For example, Daganzo and Pilachowski (2011) proposed a solution taking into account the distance between the current bus and the preceding and following buses to adjust the speed of the current bus. It includes holding buses at stations, accelerating or decelerating.

The studies carried out within the traditional fixed-line bus services handle situations where the demand is consistently strong over the territory and where the fleet is composed of high-capacity vehicles. When the demand is weaker, it is complicated to operate an economical and frequent transit system as the resources are shared by few people and are very costly (e.g. driver salaries, fuel expenses, etc.). The autonomous fleets are composed of vehicles with lower capacity, but it is easier to dynamically adapt their scheduling strategy at low cost and have access to real-time information.

2.2 Demand-Adaptive Transit Systems

Demand-Adaptive System (DAS), or Demand-Responsive Transit (DRT), is a personalized type of transportation displaying features from both fixed-line services and on-demand systems. In such systems, passengers are picked up and dropped off on-demand at predetermined stops, and unrequested stops are skipped. There are still compulsory stops, which are served within a predefined time window, but the routes are adapted based on the the requested stops. A method to determine the time windows at the compulsory stops has been proposed by Crainic et al. (2010). Li et al. (2007) depicted the advantages to substitute fixed-line bus services to DRT services in two cities in California with low demand density.

Gabriel et al. (2008) address the issues of evaluating DAS services in comparison to traditional transit services and fully on-demand systems. The transit systems' evaluation denotes the part of the planning process dedicated to the study of the behaviour and the performance of the line under various conditions with respect to demands, policies and costs. They mention the main steps of transit lines' evaluation in order to tune operating parameters impacting the system performance under different scenarios for cost-benefit analyzes: 1) the scenario, parameters and policies are specified, as well as the demand to serve 2) the line is designed 3) the operation of the line is simulated (during a specified time-horizon) 4) results are collected and performance measures are computed. The importance of demand generation in step 1) differs from one system to the other: whilst in fixed lines transits static methods are often used to simulate an average demand, dynamic methods are used to simulate the time-dependent stop-to-stop requests in on-demand systems. The performance measurements in step 4) vary as well from one system to the other: in fixed-lines the service quality is mainly represented by the buses' punctuality and the constant interarrival times whereas for on-demand systems it is expressed by the specific users' waiting time and journey time. Gabriel et al. (2008) propose a framework for evaluating DAS lines including the scenario input, the optimization modules for the design and operation of the line and the simulation module which yield the statistical information about the performance.

2.3 Vehicles Assignment to Routes

Bongiovanni et al. (2016) present an optimization approach for the autonomous vehicles scheduling within a transit system composed of circular routes. They separate the planning process in two main tasks: line planning and vehicle scheduling. Line planning corresponds to defining the routes and the required headway on each route over the planning horizon. Vehicle scheduling refers to computing a general assignment plan for each vehicle for each time period over the planning horizon of one day. It means that each vehicle is assigned to a specific route or to a recharging station for each time period. The underlying assumption is that the vehicles will not transfer between routes and charging stations too often which makes the time discretization of the planning horizon possible. They focus on the vehicle scheduling task which takes

as input the predefined routes, frequencies, fleet size and battery model. They present the scheduling problem as a mixed-integer linear programming (MILP) with battery constraints and the goal of the objective function being to maximize the total battery charge levels at the end of the planning horizon.

3 Problem Formulation

In this section we formulate the mathematical model describing the autonomous vehicles circular line system. All the variables are listed in Table 1. In addition to traditional bus transit system descriptions, we introduce the concept of battery stations and we include dynamic bookings from one station to an other station on the loop. As we have access to information during the service horizon time H, we denote a discrete timestamp t which takes values between [0, H] at fixed sampling interval.

3.1 Circular Route

The circular line in this transportation system is a route which starts at a certain station, traverses other stations once and terminates at the starting station. The route is represented by set of stations and a set of directed edges E linking each station $s \in S$ to its following station. The set of charging stations C includes stations located on the stops within the loop: $C \subset S$. The maximum speed of an edge, representing the traffic at time t, is expressed as $speed_t^e$.

3.2 Vehicles

Each vehicle composing the fleet $v \in V$ moving on the circular closed line is characterized by a capacity c^v , a maximum charge q^v , a recharge rate α^v , a battery consumption rate β^v and a maximum speed s^v . The battery level of vehicle v at the timestamp t is $I_t^v \in [0, q^v]$. The battery change between the preceding discrete timestamp and the current timestamp t is given by δ_t^v . The edge it is currently traversing is e_t^v and the distance to the next vehicle in front of it on the loop is given by $next_t^v$. The occupancy of the vehicle is expressed as $o_t^v \in [0, c^v]$. The vehicle is travelling either at its maximum speed or at the limitation of the current edge. Its current speed is therefore $\max\{s^v, speed^{e_t^v}\}$. When a vehicle is charging at a station the boolean variable x_t^v is set to 1 and it can not carry any passengers $o_t^v = 0$.

3.3 Bookings

The set B represents the users' bookings made during the service horizon. A booking $b_{i,j} \in B$ requests a trip from station i to j at time t^b for a group of n^b persons. If the booking has been satisfied, the boolean variable D_b is set to 1 and we know that it has been executed by vehicle $v^b \in V$. The pickup time of booking b at station i is p^b and drop-off time at station j is d^b . The waiting time w^b equals $p^b - t^b$ and the journey time Δ^b is $d^b - p^b$. We denote B^* the set of bookings which have been satisfied, so the bookings for which $D_b = 1$.

3.4 Output Metrics

At the end of the service horizon T, some metrics can be derived in order to evaluate the performance of the overall system dispatching the vehicles to serve the requests.

$\begin{array}{lll} S = \{1,,n\} \\ E = \{n+i,,2n\} \\ E = \{n+i,,2n\} \\ V = \{1,,v\} \\ C \subset S \\ S \in \text{ of chircles composing the fleet} \\ C \subset S \\ S \in \text{ of charging locations} \\ B = \{1,,b\} \\ S \in \text{ of bookings made during the scheduling horizon} \\ S \in S \\ S \in \text{ of bookings which have been satisfied at the end of } H \\ H \\ Length of the scheduling horizon \\ Interval \in \mathbb{R} \\ T = \{t = interval * k, k \in \mathbb{N} 0 < t < H\} \\ S \in \text{ of timestamps} \\ Maximum load capacity of vehicle } v \in V \\ Q^v \\ Q^v \\ S^v \\ S \in S \\ S^v \\ $		
$\begin{array}{lll} E = \{n+i,,2n\} & \text{Set of directed edges linking the stations} \\ V = \{1,,v\} & \text{Set of vehicles composing the fleet} \\ C \subset S & \text{Set of charging locations} \\ B = \{1,b\} & \text{Set of bookings made during the scheduling horizon} \\ B^* \subset B & \text{Set of bookings which have been satisfied at the end of } H \\ H & \text{Length of the scheduling horizon} \\ Interval \in \mathbb{R} & \text{Interval * } k, k \in \mathbb{N} 0 < t < H \} \\ C^v & \text{Maximum load capacity of vehicle } v \in V \\ A^v & \text{Maximum load capacity of vehicle } v \in V \\ Battery recharge rate of vehicle v \in V \\ Battery recharge rate of vehicle v \in V \\ Battery consumption rate of vehicle v \in V \\ Battery level of vehicle v \in V \\ Battery level of vehicle v at time t \\ Battery level of vehicle v at time t \\ Battery level of vehicle v is traversing at time t \\ Battery change between t and its preceding timestamp \\ E^v & Edge e \in E \\ which vehicle v is traversing at time t \\ Distance to the next vehicle in front of v on the loop at time t \\ Distance to the next vehicle v at time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is to vehicle v is time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is traversing at time t \\ Distance to the next vehicle v is of volume to the loop at time t \\ Distance to the next vehicle v is of volume vehicle v is charging at a station at time t, 0 otherwise \\ Time at which the request b \in B has been made \\ Pick-up timestamp of booking b \\ Ualting time $		Signification

Table 1: Problem sets and parameters

Energy

The total energy consumed by a vehicle v is the sum of the battery changes over the scheduling horizon when the vehicle is not charging:

$$energy^v = \sum_{t \in T} \delta_t^v * (1 - x_t^v)$$

The total energy cost for the entire system is therefore the sum of the energy consumption of each vehicle composing the fleet:

$$energyCost = \sum_{v \in V} energy^v$$

Occupancy

The average occupancy of a vehicle v over the scheduling horizon T is given by:

$$avgOccupancy = \frac{\sum_{t \in T} o_t^v}{|T|}$$

The average occupancy does not take into account of the time vehicles spend at charging stations and therefore can not carry any passenger. As explained in section 2.1, a common unit used in transportation measurement is the load factor, which expresses the efficiency of a vehicle based on the kilometres travelled by passengers over the total kilometres that could have been driven considering its maximum capacity. In our case, as we are mainly interested in how the energy of the vehicles has efficiently been used, we define the passenger-energy measure: it is the energy that has been consumed by the vehicle during the passenger journey time. The passenger-energy for one vehicle is therefore the sum of the passenger-energy of the bookings it has satisfied. The seat-energy available represents the maximum possible passenger-energy if the vehicle would have been always full: it is the energy consumption of the vehicle times its maximum capacity. The vehicles' load factor is its passenger-energy over its seat-energy:

$$loadFactor^{v} = \frac{\sum_{t \in T} \delta_{t}^{v} * (1 - x_{t}^{v}) * o_{t}^{v}}{energy^{v} * c^{v}}$$

We can compute the average load factor of the fleet as:

$$avgLoadFactor = \frac{\sum_{v \in V} loadFactor^{v}}{|V|}$$

We denote the stability load factor the difference between the maximum load factor among the vehicles composing the fleet and the minimum one. The closer it is to 0 the better as it implies that all vehicles are used equivalently: $stabilityLoadFactor = \max_{v^+ \in V} loadFactor^{v^+} - \min_{v^- \in V} loadFactor^{v^-}$.

Waiting Time

The average waiting time among the satisfied bookings is given by:

$$avgWaitingTime = \frac{\sum_{b \in B*} w^b}{|B^*|}$$

The stability waiting time is the difference between the maximum waiting time and the minimum waiting time among the bookings: $stabilityWaitingTime = \max_{b^+ \in B^*} w^{b^+} - \min_{b^- \in B^*} w^{b^-}$.

Journey Time

The average journey time among the satisfied bookings is given by:

$$avgJourneyTime = \frac{\sum_{b \in B*} \Delta^b}{|B^*|}$$

Completed Bookings Percentage

Travel time, booking time, At the end of the scheduling horizon, some bookings may not have been satisfied. The percentage of bookings which have been satisfied is given by:

$$completedBookings = \frac{|B^*|}{|B|}$$

4 Methodology

In order to evaluate the behaviour and performance of the system under various conditions with respect to the line configurations, the booking scenarios and the vehicles scheduling alternatives, we undertake analyses under laboratory conditions by simulating the the operation of the system on the platform dispatching the vehicles. One of our main goal in the analysis we conduct on the line is to get measures as close as possible to real world conditions. In order to achieve this, a dynamic system is required which handles the time-dependent events of the system. In section 4.1 we describe the behaviour of the different interconnected services simulating the vehicles' behaviour reacting to external conditions and how the overall system is evaluated. In section 4.2 we present the variations of scheduling strategies used to dispatch the vehicles on the line.

4.1 Simulation Framework

Figure 1: Interconnected modules composing the simulation framework

Figure 1 illustrates the different web services and how they are linked to each others. In what follows we describe the behaviour of each module and the simulation parameters which can be tuned. - Deileon simulator for the vehicles => register the vehicles, handle battery, send TCP messages with hermes - World-simulator starting the vehicles, sending the edge speeds and bookings -

World Simulator

The world-simulator is the web service which is used to start the simulation, send the booking requests and send updates of traffic information. At the beginning of the simulation, it sets the time control to a given ratio which is broadcasted to the other web services in order to synchronize them. A day can be simulated in m minutes which corresponds to a ratio r of m/24h. The world-simulator is instantiated with a scenario describing the external events which affect the overall system.

Simulated Vehicles

start: spread on the line, battery is full starting location they cannot take over other vehicles, need to follow the loop unless when they go to charge they don't compute the headway and go max speed

Reported Metrics

Logs fetched from database - vehicle logs - journey logs - output graph

4.2 Scheduling

Why we don't follow exactly luts: adapt the vehicles on the fly on one fixed route

4.2.1 Vehicles' Activities Schedule

when they arrive at station, if they can they pick up the booking (based on booking size) they drop off bookings that finish here they wait based on headway computation *battery* check if it is under threshold finish to drop off everybody and go to charging station

4.2.2 Headway

compute headway based on fleetorchestrationservice

4.2.3 Dynamic Fleet Size

how choose vehicles to send to charge and which ones to activate

5 Numerical Experiments

Real environment

5.1 Simulation Settings

tuning speed of actors logs fetched from db

5.2 Graph

Unless stated, charging locations at same place

5.3 Optimal Headway

5.4

5.5 Simulated Demand

5.6

6 Conclusion
